TITLE: MINI AMMONIA PLANT

CROSS-REFERENCE TO RELATED APPLICATIONS

This application claims the benefit of Provisional Patent Application (PPA) No. 60/466,200, filed on April 29, 2003 by the present inventors.

FEDERAL SPONSORED RESEARCH Not Applicable

FIELD OF THE INVENTION

This invention involves a mini-ammonia production plant using natural gas as its feedstock. Its primary application is to supply gaseous ammonia to a power plant's selective catalytic reduction (SCR) reactor or selective non-catalytic reduction (SNCR) system for NO_x reduction in flue gas streams. It also has applications in distributed ammonia production for agricultural or industrial purposes.

BACKGROUND OF THE INVENTION

Ammonia is the reagent used in NO_x reduction for flue gas streams. In the SCR, ammonia vapor is injected upstream of the SCR catalyst modules, where it will react with

NO_x to form elemental nitrogen and water vapor. This same reaction will occur in the SNCR process, but with less conversion efficiency. SCR with ammonia is capable of >90% NO_x removal, while SNCR has a removal efficiency of about 50%.

Currently, ammonia needed for SCR or SNCR is supplied from one of the following sources: anhydrous ammonia, aqueous ammonia, or on-site generation using the urea hydrolysis process. Anhydrous ammonia is a hazardous material, and on-site bulk storage is not allowed in most areas. Aqueous ammonia which contains mostly water is expensive for this application. Ammonia from urea has the highest operating cost due to the high cost of urea, but it is a safe system because it eliminates the need for ammonia storage.

Industrial ammonia is generally manufactured in large capacity plants (1000 tons per day or larger) using natural gas as its feedstock. However, for utility-size gas turbines in the U.S. (150 MW power output or larger), less than 2 tons per day of ammonia vapor is needed for SCR NO_x control. Even with a 350 MW coal-fired unit, only about 5 tons per day of ammonia is needed for SCR. Ammonia plants at these sizes do not exist because the ammonia manufacturing process is complex, and economical production of such a small quantity of ammonia is not feasible at present.

SCRs require the use of diluted ammonia vapor. When air is used as a diluent, the ammonia/air mixture needs to be heated so that it does not cool the flue gas entering SCR and degrade its effectiveness. Ammonia production creates excess waste heat and could be used for this heating purpose. The process design in this invention employs a method of using waste heat from ammonia synthesis reactors to generate a hot ammonia and air mixture for feeding SCR.

Either anhydrous ammonia or aqueous ammonia can be produced in this design. For SCR applications, the anhydrous ammonia option is a better design because it is simpler and less costly. For distributed ammonia generation for other applications, generation of aqueous ammonia may have advantages due to its ease of storage and transportation.

The commercial ammonia production technology requires a minimum of over 1000 tpd capacity to be economical. This invention provides a unique method of making only a few tons per day of ammonia economically. The process includes novel thermal integration schemes that produces refrigeration for ammonia condensing and recovers the waste heat from reactors to heat the product gas.

SUMMARY OF INVENTION

The present invention provides a method and apparatus for generating a small amount of ammonia on-site from natural gas feedstock. This invention eliminates the need to import ammonia or urea and replaces it with low-cost on-site generation.

A packaged natural gas-to-hydrogen plant is employed as the source of hydrogen and nitrogen for ammonia production. The small hydrogen plant has been developed recently by various hydrogen fuel cell developers. The effluent gas from the hydrogen plant contains impurities including mainly carbon oxides, water vapor, and excess nitrogen. A pressure swing adsorption gas treating system is employed to clean up these impurities and remove excess nitrogen to maintain a hydrogen-to-nitrogen ratio of 3:1. This molar ratio is required for the ammonia synthesis reaction.

The clean gas is then compressed before entering the methanation reactor; where the residual carbon dioxide and carbon monoxide are removed by converting them to methane and water vapor.

The carbon oxide free gas is then compressed in a charge compressor to a desired pressure and heated before entering a multi-stage (2 to 3) ammonia synthesis reactor. The ammonia synthesis reaction is exothermic. At the exit of the reactors, a cooled recycle gas is injected to control the reactor temperature.

The reactor effluent gas is first cooled through heat exchange with the inlet gas. Additional coolers are used to cool the gas before it enters the ammonia condenser. The

condensed ammonia is collected in the ammonia knockout drum. The drum's overhead vapor is recycled back to the charge compressor inlet and to provide cooling gas for reactor inter-stage cooling. A small amount of gas is purged through a membrane separator, where hydrogen is separated for recycle and the remaining purged gas is vented to the product gas stream. The condensed ammonia is withdrawn from the ammonia knockout drum through a Joule-Thomson valve or a capillary tube, where the liquid ammonia expands to provide chilling for the ammonia condenser. The product ammonia gas is heated by recovering reactor waste heat or it is mixed with a hot dilution air (heated by recovered reactor waste heat) for use in SCR as the reagent for NO_x reduction.

The advantages of this on-site ammonia generation are:

- Eliminate the need for importing ammonia to the ammonia users
- Provides pre-conditioned hot ammonia gas or hot ammonia/air mixture to meet the SCR feed gas requirements
- The purge gas streams from gas treating and ammonia condenser are included in the product gas to eliminate emissions from the system
- In most cases, this system is expected to have an economic advantage over importing ammonia or making it through urea hydrolysis.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a process flow diagram of a preferred embodiment of the present invention. It is designed for use in supplying diluted ammonia air mixture for power plant SCR systems.

Figure 2 is a process flow diagram of an alternative embodiment of the present invention. It is designed for use in supplying hot ammonia vapor (to 300⁰F or higher) for use in SCR. The hot ammonia design eliminates the need for heating the air/ammonia mixture before entering SCR.

Figure 3 is another alternative embodiment. It is used to generate pure ammonia at normal ambient temperature for industrial applications. In this case, the purge gas is vented or burned in a furnace.

DETAILED DESCRIPTION OF THE INVENTION

Figure 1 depicts a flow diagram for the production of ammonia with dilution air for SCR or SNCR applications. Streams 1, 2, and 3 are natural gas fuel, water, and air supply, respectively. These are feed streams to the packaged hydrogen plant 4. The main component in the hydrogen plant is a steam reformer or a partial oxidation reformer. In the preferred embodiment, a catalytic partial oxidation reformer (CPOX) is used, but other non-catalytic partial oxidation (POX) or steam reformers can also be employed. In the catalytic or non-catalytic partial oxidation reformer, air is used as the oxidant. If a steam reformer is used, a separate nitrogen plant is needed. The reaction product from POX or CPOX contains hydrogen, carbon monoxide, carbon dioxide, nitrogen, and water vapor. This reaction product is further processed by water shift reaction to convert carbon monoxide to hydrogen and carbon dioxide. The hydrogen plant effluent gas contains hydrogen, nitrogen, carbon dioxide, water vapor, and a trace amount of un-reacted carbon monoxide.

A gas treating system 5 is employed to remove carbon dioxide and to adjust nitrogen content in the gas stream. A pressure swing adsorption (PSA) type gas treating system is preferred for this application. Other carbon dioxide removal processes such as an amine system can also be used in lieu of the PSA system. The PSA system is designed to provide a hydrogen to nitrogen ratio of approximately 3:1 in the treated effluent gas stream. If an amine system is used, a larger downstream ammonia synthesis reactor purge system is needed, as amine does not remove nitrogen. Since the treated gas from 5 still contains a trace amount of carbon monoxide and carbon dioxide, a methanation system 6 is used to convert these compounds to methane and water vapor. Methanation is a commercial technology used in existing ammonia manufacturing facilities for the same purpose.

The methanation system exit gas is compressed by a charge compressor **7** to a high pressure of about 170 bar. The compressor discharge gas is heated in an ammonia synthesis reactor outlet gas/inlet gas heat exchanger **8** and a trim heater **9**. The trim heater **9** is also used as a startup heater. The heated gas is then fed to two- or three-stage ammonia synthesis pipe reactors. In this figure, three reactors **10**, **11**, and **12** are used. These reactors are filled with ammonia catalyst that promotes the reaction of hydrogen and nitrogen to become ammonia. Since the ammonia synthesis reaction is an exothermal reaction, a cold gas is mixed at the first and second reactor exit gas to maintain a suitable reactor inlet gas temperature for the subsequent stages. The final reactor outlet gas contains 17 to 25% of ammonia gas and the remaining are un-reacted hydrogen and nitrogen. This reactor outlet gas is cooled by heat exchanger **8** and then followed by the SCR dilution air heater **13**, where the hot gas is cooled by dilution air from the dilution air blower **18**. Heat exchanger **13** effluent is further cooled in the ammonia condenser **14**. In the condenser, ammonia is cooled and condensed and is collected in the ammonia knockout drum **15**. The non-condensable gas from the ammonia knockout drum **15** enters the suction side of the recycle compressor **20** for recycle back to the heat exchanger **8**. A portion of this recycle gas is used as reactor cooling gas. A purge stream from the ammonia knockout drum **15** is sent to a membrane separator **17**, where hydrogen is separated for recycle back to the charge compressor **7** inlet, and the hydrogen depleted purge gas is sent to a purge gas line **19**. The purge gas **19** can be combined with diluted ammonia product stream **21** and exported to SCR. From the knockout drum, a small stream of ammonia liquid **24** is withdrawn and sent to a small on-site storage day tank (not shown).

The liquid anhydrous ammonia collected in the ammonia knockout drum **15** is stored under high pressure of 2000 to 2500 psig. During normal operation, the stored liquid ammonia expands through a Joule Thompson expansion valve **16**. This ammonia expansion from high pressure to a low pressure (50 to 100 psig) produces a refrigeration effect that provides cooling for the ammonia condenser **14**. The expanded ammonia gas is mixed with dilution air before it is sent out to SCR in the ammonia supply line **21**. A

dilution air supply is required because most SCR manufacturers require the reaction gas to contain only 5% of gaseous ammonia.

Figure 2 depicts a flow diagram for the production of hot ammonia gas, without the dilution air, for SCR or SNCR applications. In this embodiment, an ammonia gas superheater **25** is used downstream of heater **8**. A trim cooler **22** is used to further cool the reactor exit gas. Cooler **22** may be a water-cooled heat exchanger or an air-fan cooler. Cooled reactor effluent gas then enters ammonia condenser **14**. The purge gas stream **19** is combined with the hot ammonia product gas **23** for use in SCR. In this design, the dilution air is not provided in the mini ammonia plant design. This alternative is suitable for long distance transport of ammonia gas, as it is more economical to transport ammonia gas than the diluted ammonia/air mixture.

Figure 3 depicts a flow diagram for the production of pure ammonia for industrial applications. In this case, purge gas streams from the gas treating system **5** and purge gas membrane **17** are combined to stream **19**, and vented or burned in a furnace. The product gas **23** is not mixed with any purge gas and is a pure ammonia stream.
